54 Sampling frequency converting device and memory address control device.

57 A sampling frequency converting device is disclosed. A memory unit stores an input signal  $D_{si}$  having an input sampling frequency  $F_{si}$ . An interpolation unit interpolates the readout signal from the storage unit. A sampling frequency ratio detection unit detects the current sampling frequency ratio  $R_n$  between the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$  and detects a new sampling frequency ratio  $R_{n\text{ NEW}}$  based on the current sampling frequency ratio  $R_n$  and a past detected value  $R_{n-1}$  preceding the current detected value by one detection period. A control unit having the sampling frequency detection unit controls the storage unit and the interpolating unit from the new sampling frequency ratio  $R_{n\text{ NEW}}$ . Since the present sampling frequency converting device is not susceptible to accumulation of re-sampling time address errors even if the sampling frequency ratio continues to be changed for a pre-set time duration, the capacity of the storage unit is not increased, while there is no necessity of restricting the speed or amount of change in the sampling frequency ratio.

## BACKGROUND OF THE INVENTION

This invention relates to a sampling frequency converting device for converting the sampling frequency of input signals into an arbitrary sampling frequency by re-sampling, and a memory address control device for controlling the address used when reading out data from a memory unit.

Recently, digital audio signal reproducing devices for transmitting audio signals over an optical cable or a coaxial cable as digital signals and reproducing the digital audio signals via a digital audio interface have become popular. With such digital audio signal reproducing devices, a phase locked loop (PLL) made up of a phase comparator and a voltage controlled oscillator (VCO) is employed for generating clocks from received digital audio signals. However, with such digital audio signal reproducing device, digital/analog (D/A) conversion characteristics tend to be lowered due to jitter introduced by the VCO in the PLL. Consequently, with a device for reproducing a digital audio signal recording medium, such as a compact disc (CD) player or a digital audio tape (DAT) player, there are occasions wherein satisfactory distortion-free audio signals may be produced by converting the digital audio signals into analog audio signals by D/A conversion using quartz clocks and the resulting analog audio signals are subsequently transmitted.

On the other hand, with a recording medium acting as a source for digital audio signals, such as CD, an optical disc smaller in size than CD, DAT or a digital audio tape smaller in size than DAT, the sampling frequency during recording of digital audio signals is not unified and may be any one of 44.1 kHz, 48 kHz or 32 kHz. With satellite broadcast (BS) which is not a recording medium but acts as a source for digital audio signals, the sampling frequency may be any one of the above-given sampling frequencies. Consequently, for recording the digital audio signals from DAT or BS on a small-sized optical disc with the sampling frequency of 44.1 kHz, the digital audio signals from DAT or BS with the sampling frequency of 48 kHz need to be converted into analog signals by D/A conversion and subsequently re-converted into digital audio signals with the sampling frequency of 44.1 kHz by analog/digital (A/D) conversion, thus inevitably producing deterioration in characteristics due to distortion.

On the other hand, in mixing-recording digital audio signals using a DAT, respective digital audio signals to be mixed need to be converted into analog signals before proceeding to mixing if the different digital audio signals differ in the sampling frequency or in synchronization methods.

For preventing deterioration in playback digital audio signals due to deterioration in performance due to clock jitter or difference in sampling frequencies for realizing free sampling frequency conversion, it has been desired to develop a non-synchronization type sampling frequency conversion device.

In general, such sampling frequency converting device exploits re-sampling time addresses for specifying re-sampling points for re-sampling a signal entered at a sampling frequency  $F_{si}$  with a sampling frequency of  $F_{so}$ . These re-sampling time addresses are generated in dependence upon the ratio of the sampling frequency of input signals (input sampling frequency)  $F_{si}$  to the sampling frequency of re-sampled signals (output sampling frequency)  $F_{so}$ .

In general, the present sampling frequency converting device employs the re-sampling time addresses for specifying the re-sampling points for re-sampling the input signal having the sampling frequency  $F_{si}$ . The re-sampling time addresses are generated depending on the ratio of the sampling frequency of the input signal (input sampling frequency)  $F_{si}$  and the sampling frequency of re-sampled signals (output sampling frequency)  $F_{so}$ .

Specifically, the period  $t (= N \cdot T_{so})$  equal to  $N$  times the period of the output sampling frequency  $F_{so}$  (output sampling frequency) is counted with input reference clocks equal to  $M$  times the input sampling frequency  $F_{si}$  (input master clocks) or  $MCK_i (= M \cdot F_{si})$  to find the sampling frequency ratio  $R$  between the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$ , at the same time as jitter components such as  $F_{si}$ ,  $MCK_i$  or  $F_{so}$  are removed on averaging. The sampling frequency ratio  $R$  and the re-sampling time are cumulatively added together to generate the re-sampling time address. The re-sampling points stored in the re-sampling buffer memory are read out in accordance with the re-sampling time addresses for converting the sampling frequency.

Meanwhile, for such application in which the input sampling frequency  $F_{si}$  or the output sampling frequency  $F_{so}$  are changed, there arises the inconvenience that an error tends to be transiently produced between the value of the sampling frequency ratio  $R$  and the actual ratio of  $F_{si}/F_{so}$ .

Consequently, high-precision conversion is realized under a condition of the constant input sampling frequency  $F_{si}$  or the constant output sampling frequency  $F_{so}$ .

In addition, if the sampling frequency ratio continues to be changed for a pre-set time, the re-sampling time address errors tend to be accumulated under the effect of the temporal difference  $\Delta R$  of the sampling frequency ratio shown in Fig.1, such that the buffer memory capacity is exceeded, thus leading to limitations imposed on the speed and amount of change of the sampling frequency ratio or to increased buffer memory

capacity.

On the other hand, it may be felt that the re-sampling time address resolution may be improved by increasing the frequency of the input master clocks  $MCK_i$  without the necessity of increasing the detection period  $t_d$ . However, in such case, the problem of limitations imposed on the operating speed of the circuit such as counters or of absorption and removal of input clock jitter. Thus it has not been possible to prevent errors from being accumulated by simply increasing the frequency of the input master clocks  $MCK_i$  for improving the re-sampling time address resolution, although the errors may thereby be reduced.

In addition, if, for performing frequency conversion with the above-described sampling frequency converting device, the power source is turned on, signal input/output is changed over, the noise is mixed or the input/output sampling frequency is rendered variable, the data write address for writing data in the re-sampling buffer memory or the data readout address for reading out data from the buffer memory approach or cross over each other, thus producing a non-continuous noise from the sampling frequency converting device.

For stabilizing the sampling frequency converting operation, it is necessary to initialize the memory readout addresses so that the absolute value of the difference between the write address and the readout address of the re-sampling buffer memory reaches its maximum value after stabilization of the operation of sampling frequency ratio detection for detecting the sampling frequency ratio. However, the initialization of the memory readout addresses is an operation difficult to achieve and signal interruption or noise tend to occur during the converting operation.

## OBJECTS AND SUMMARY OF THE INVENTION

It is an object of the present invention to provide a sampling frequency converting device which resolves the above problems.

It is another object of the present invention to provide a sampling frequency converting device which is capable of eliminating the initializing operation during power on, signal input/output changeover, noise or variable input/output sampling frequency, and also of preventing signal interruption or noise during the converting operation.

In one aspect, the present invention provides a device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising storage means for storing the input signal; interpolation means for interpolating the signal read out from said storage means, and control means for generating a first sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency and a second sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency based on the first sampling ratio for suppressing jitter components and for performing sampling frequency conversion. The control means generates a control signal for controlling the address signal of the storage means and the interpolation factors of the interpolation means and for effecting sampling frequency conversion by controlling the storage means and the interpolation means based on the generated address signal and the control signal.

In another aspect, the present invention provides a device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising storage means for storing the input signal, interpolation means for interpolating the signal read out from the storage means, sampling frequency ratio detection means for detecting the sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency over a short term and over a long term, and control means for controlling the storage means and the interpolation means responsive to the sampling frequency ratio over the short time period and the sampling frequency ratio over the long time period from the sampling frequency ratio detection means.

In a further aspect, the present invention provides a device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising storage means for storing the input signal, interpolation means for interpolating the signal read out from the storage means, sampling frequency ratio detection means for detecting the sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency and for detecting a new sampling frequency ratio based on the detected value and a past detected value, and control means for controlling the storage means and the interpolation means based on the new sampling frequency ratio from the sampling frequency ratio detection means.

In a further aspect, the present invention provides a device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising storage means for storing the input signal with the difference between the write address and the readout address being changed arbitrarily, interpolation means for interpolating the signal read out from said storage means, and memory address control means for controlling the readout addresses from the storage means responsive to the sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency.

In yet another aspect, the present invention provides a memory address control device for a ring buffer memory for recording and reproducing data, with the difference of the readout address being arbitrarily changed with respect to the write address. The memory access control device comprises address difference detection means for detecting the difference between the write address and the readout address of the ring buffer memory, and readout address optimization control means for optimally controlling the readout address for controlling the address difference detected by the address difference detection means.

#### DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

Referring to the drawings, preferred embodiments of the sampling frequency converting device and the memory address controller according to the present invention will be explained in detail.

The first embodiment will be explained first of all with reference to Fig.2.

The present first embodiment is directed to a sampling frequency converting device of converting an input signal  $D_{si}$  having a sampling frequency  $F_{si}$  at an input terminal 1 into a signal  $D_{so}$  having an arbitrary sampling

frequency  $F_{so}$  by re-sampling, and realizes sampling frequency conversion in which the input system is completely asynchronous with respect to the output system, that is sampling frequency conversion of a free conversion ratio without the relation of synchronicity between input and output signals. In the following description, the sampling frequency  $F_{si}$  of the input signal  $D_{si}$  is referred to as the input sampling frequency  $F_{si}$ , while the arbitrary sampling frequency  $F_{so}$  is referred to as the output sampling frequency  $F_{so}$ .

The present sampling frequency converting device has a re-sampling buffer memory 2 for writing and reading the input signal  $D_{si}$  of the input sampling frequency  $F_{si}$  entering at the input terminal 1, and an interpolation circuit 3 for interpolating an output signal of the re-sampling buffer memory 2. The sampling frequency converting device also has a control unit 9 for detecting the current sampling frequency ratio  $R_n$  from the input sampling frequency  $F_{si}$  supplied at an input terminal 6 and the output sampling frequency  $F_{so}$  supplied from the input terminal 6, generating a new sampling frequency ratio  $R_{n\text{ NEW}}$  based upon the current detection value  $R_n$  and a past detection value  $R_{n-1}$  preceding the current value by one detection period, producing a control signal controlling an interpolation factor of the interpolation circuit 3 and the address signal of the re-sampling buffer memory 2 based on the new sampling frequency ratio  $R_{n\text{ NEW}}$ , and controlling the re-sampling buffer memory 2 and the interpolation circuit 3 based on the generated address signal and the control signal for performing the sampling frequency conversion. The interpolation circuit 3 outputs the signal  $D_{so}$  having the output sampling frequency  $F_{so}$  at an output terminal 4 under control by the control unit 9.

The control unit 9 has a sampling frequency ratio detection circuit 7, and an address control signal generating circuit 8. The sampling frequency ratio detection circuit 7 detects the current sampling frequency ratio  $R_n$  from the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$  and generates the new sampling frequency ratio  $R_{n\text{ NEW}}$  based on the current detection value  $R_n$  and the past detection value  $R_{n-1}$  preceding the current value by one detection period. The address control signal generating circuit 8 generates a control signal for controlling an address signal for the re-sampling buffer memory 2 and a control signal controlling the interpolation coefficient of the interpolation circuit 3 based upon the new sampling frequency ratio  $R_{n\text{ NEW}}$  detected by the sampling frequency ratio detection circuit 7.

The sampling frequency ratio detection circuit 7 subtracts the past detected value  $R_{n-1}$  from twice the current sampling frequency ratio  $R_n$  to find a new sampling frequency ratio  $R_{n\text{ NEW}}$ . This is equivalent to adding a difference  $\Delta R_n$  between the current sampling frequency ratio  $R_n$  and the past detected value  $R_{n-1}$  to the current sampling frequency ratio  $R_n$  to find the new sampling frequency ratio  $R_{n\text{ NEW}}$  as shown in Fig.3. That is, the new sampling frequency ratio  $R_{n\text{ NEW}}$  is given by

$$R_{n\text{ NEW}} = R_n + \Delta R_n + (R_n - R_{n-1}) = 2R_n - R_{n-1} \quad (1)$$

This new sampling frequency ratio  $R_{n\text{ NEW}}$  is supplied to the address control signal generating circuit 8.

The address control signal generating circuit 8 is responsive to the new sampling frequency ratio  $R_{n\text{ NEW}}$  to generate a re-sampling time address as a data readout address which is supplied to the re-sampling buffer memory 2. The address control signal generating circuit 8 also transmits the data write address to the re-sampling buffer memory 2. The address control signal generating circuit 8 transmits a data write address to the re-sampling buffer memory 2. The address control signal generating circuit is also responsive to the new sampling frequency ratio  $R_{n\text{ NEW}}$  to generate an over-sampling factor selection control signal used for over-sampling carried out in the interpolation circuit 3 and leading and trailing linear interpolation factors for linear interpolation (LIP.F.L and LIP.F.T.).

The interpolation circuit 3 is responsive to the re-sampling time addresses to process output data of the re-sampling buffer memory 2 with, for example, FIR filtering to produce two neighboring high-order interpolation data corresponding to the re-sampling time address to generate the signal  $D_{so}$  having an output sampling frequency  $F_{so}$  by linear interpolation of the two data based on the over-sampling factor selection control signal and the leading and trailing linear interpolation factors for linear interpolation (LIP.F.L and LIP.F.T.).

The sampling frequency converting device thus causes the sampling frequency ratio detection circuit 7 of the control unit 9 to detect the new sampling frequency ratio  $R_{n\text{ NEW}}$  and causes the address control signal generating circuit 8 to generate the control signal for controlling the re-sampling time address and the interpolation factors based on the new sampling frequency ratio  $R_{n\text{ NEW}}$ . Thus it is possible with the present sampling frequency converting circuit to perform sampling frequency conversion by stable interpolation by the interpolation circuit 3 without producing overflow or underflow in the re-sampling buffer memory 2 or increasing the capacity of the re-sampling buffer memory 2.

Referring to Figs.4 to 6, a second embodiment of the present invention will be explained.

The second embodiment is directed to a sampling frequency converting device of re-sampling the sampling frequency  $F_{si}$  of the input signal  $D_{si}$  at an input terminal 11 into the signal  $D_{so}$  having an arbitrary sampling frequency  $F_{so}$ , and realizes sampling frequency conversion in which the input system is completely asynchronous with respect to the output system, that is sampling frequency conversion at a free conversion ratio without the relation of synchronicity between input and output signals. In the following description, the sampling frequency

$F_{si}$  of the input signal  $D_{si}$  is referred to as the input sampling frequency  $F_{si}$ , while the arbitrary sampling frequency  $F_{so}$  is referred to as the output sampling frequency  $F_{so}$ .

Referring to Fig.4, the present sampling frequency converting device has a  $8F_{si}$  over-sampling filter 12 for over-sampling the input signal  $D_{si}$  entering at the input terminal 11 into the signal of a frequency  $8F_{si}$  and a re-sampling buffer memory 13 for writing and reading the input signal now having the frequency  $8F_{si}$  for over-sampling. The sampling frequency converting device also has an interpolation circuit 14 for interpolating an output signal of the re-sampling buffer memory 13, and a control unit 26. The control unit measures the current sampling frequency ratio  $R_n$  which is improved in resolution by counting the period  $t (= N \cdot T_{so})$  which is  $N$  times as large as the period  $T_{so}$  of the sampling frequency  $F_{so}$  (output sampling period) supplied at an input terminal 23 with input reference clocks (input master clocks)  $MCK_i (= M \cdot F_{si})$  supplied at an input terminal 22 at a frequency equal to an integer number times the sampling frequency  $F_{si}$  to find a new sampling frequency ratio  $R_{n \text{ NEW}}$  based upon the current sampling frequency ratio  $R_n$  and the past detection value  $R_{n-1}$  preceding the current value by one detection period. The control unit also generates a control signal controlling the interpolation factors for the interpolation circuit 14 and the address signal for the re-sampling buffer memory 13 responsive to the new sampling frequency ratio  $R_{n \text{ NEW}}$  and controls the re-sampling buffer memory 13 and the interpolation circuit 14 based upon the address signal and the control signal to perform the operation of sampling frequency conversion. The sampling frequency converting device also has a re-sampling frequency signal outputting circuit 19 and a band-limiting filter 20. The re-sampling frequency signal outputting circuit 19 sub-samples the sampling frequency of the output signal from the interpolation circuit 14 having the interpolation operation controlled by the control unit 26 to produce an output sampling frequency  $F_{so}$  having the frequency values equal to two, four or eight times the sampling frequency and selects one of these frequency values by a multiplexor 19a. The band-limiting filter 20 band-limits the output signal from the re-sampling frequency signal outputting circuit 19 and outputs the output signal  $D_{so}$  having the output sampling frequency  $F_{so}$  at an output terminal 21.

The digital signal with the sampling frequency of  $8F_{si}$ , produced by the  $8F_{si}$  over-sampling filter 12, enters the re-sampling buffer memory 13, as described above. The re-sampling buffer memory 13 is a 20-bit 64-word buffer memory, by way of an example, and has the sampling frequency time equal to eight times the input sampling frequency time.

The control unit 26 has a sampling frequency ratio detection circuit 24 and an address control signal generating circuit 25. The sampling frequency ratio detection circuit 24 detects the current sampling frequency ratio  $R_n$  improved in resolution by counting the period  $t (= N \cdot F_{so})$  supplied from the input terminal 23 at the input master clock  $MCK_i (= M \cdot F_{si})$  supplied at the input terminal 22 and finds the new sampling frequency ratio  $R_{n \text{ NEW}}$  based on the current sampling frequency ratio  $R_n$  and the past detection value  $R_{n-1}$  preceding the current value by one detection period. The address control signal generating circuit 25 generates a control signal controlling the interpolation factor of the interpolation circuit 14 and the address signal of the re-sampling buffer memory 13 based on the new sampling frequency ratio  $R_{n \text{ NEW}}$ .

The sampling frequency ratio detection circuit 24 includes a counter 30 for counting the sampling frequency  $N \cdot T_{so}$  of the period entering at the input terminal 23 by the input master clock  $MCK_i$ , and an arithmetic-logic unit 31 for finding a new sampling frequency ratio  $R_{n \text{ NEW}}$  based on the current sampling frequency ratio  $R_n$  which is the count output of the counter 30, as shown in Fig.5.

The arithmetic-logic unit 31 doubles the current sampling frequency ratio  $R_n$  to produce  $2R_n$  and subtracts the past sampling frequency ratio  $R_{n-1}$  from  $2R_n$  to find the new sampling frequency ratio  $R_{n \text{ NEW}}$ .

The address control signal generating circuit 25 cumulatively adds the values of the new sampling frequency ratio  $R_{n \text{ NEW}}$ , outputted by the arithmetic-logic unit 31, using an addition circuit 32 and a flip-flop circuit 33, to generate a data readout address for the re-sampling buffer memory 13. The address control signal generating circuit is also responsive to the new sampling frequency ratio  $R_{n \text{ NEW}}$  to generate an over-sampling factor selection control signal used for over-sampling carried out in the interpolation circuit 14 and leading and trailing linear interpolation factors for linear interpolation (LIP.F.L and LIP.F.T.).

The data readout addresses, over-sampling factor selection control signals and linear interpolation factors are arranged as an upper bit range data, a mid bit range data and a lower bit range data of a data string and are outputted from the address control signal generating circuit 25.

The flip-flop circuit 33 is preferably a D-flip-flop.  $8 F_{so}$  clocks are supplied from an input terminal 34 in keeping with the sampling frequency  $8 F_{so}$  of the output signals of the second embodiment. If the sampling frequency of the output signals is 4 or  $2F_{so}$ , 4 or  $2F_{so}$  clocks are supplied, while an initializing signal  $S_E$  is supplied at an input terminal 35.

Referring to Fig.4, the interpolation circuit 14 has a leading FIR filter for the leading linear interpolation factor 15 and a trailing FIR filter for the trailing linear interpolation factor 17 for over-sampling data read out by the address control signal generating circuit 25 from the re-sampling buffer memory 13 and processing the

data with over-sampling. The interpolation circuit also has a factor ROM 16 for supplying the over-sampling factors to the leading FIR filter for the leading linear interpolation factor 15 and the trailing FIR filter for the trailing linear interpolation factor 17 and an addition circuit 18 for adding an output signal of the leading FIR filter for the leading linear interpolation factor 15 and an output signal of the trailing FIR filter for the trailing linear interpolation factor 17. The factor ROM 16 has e.g. 32 24-bit 7-word over-sampling factors.

Referring to Fig.6, the operation of the interpolation circuit 14 is now explained.

The re-sampling buffer memory 13 is responsive to the readout address supplied from the address control signal generating circuit 25 to transmit e.g. seven data at  $T_{s_i}/8$  to the leading FIR filter for the leading linear interpolation factor 15 and the trailing FIR filter for the trailing linear interpolation factor 17 as shown in Fig.6A. The leading FIR filter for the leading linear interpolation factor 15 and the trailing FIR filter for the trailing linear interpolation factor 17 convolves e.g. seven data supplied from the re-sampling buffer memory 13 with e.g. seven factors supplied from the factor ROM 16 to generate 256  $F_{s_i}$  data.

Fig.6B shows two adjacent data of these 256  $F_{s_i}$  data. An area  $E_1$  enclosed by a broken line in Figs.6A and 6B is  $T_{s_i}/8$ , while an area  $E_2$  enclosed in a broken line in Fig.6B is two adjacent data of the 256  $F_{s_i}$  at an interval of  $T_{s_i}/8$ .

The leading FIR filter for the leading linear interpolation factor 15 and the trailing FIR filter for the trailing linear interpolation factor 17 then multiply the two adjacent data at the interval of  $T_{s_i}/256$  by the linear interpolation factors supplied from the address control signal generating circuit 25. A filter output of the leading FIR filter for the leading linear interpolation factor 15 and a filter output of the trailing FIR filter for the trailing linear interpolation factor 17 are added together at the addition circuit 18. Thus the linear interpolation as shown in Fig.6C is executed.

By repeating the over-sampling and the linear interpolation, the present conversion device generates data  $D_{s_o}$  having the sampling frequency  $F_{s_o}$  as shown in Fig.6D.

The linear interpolation is now explained.

Among the linear interpolation factors, there are the leading linear interpolation factor 15 and the trailing linear interpolation factor 17. These linear interpolation factors are generated using lower-order bits, e.g. 12 bits, of a data string (data value) produced by accumulating the values of the new sampling frequency ratio  $R_{n\text{ NEW}}$  by the address control signal generating circuit 25. Specifically, the leading linear interpolation factor is given as 1's complement data of the lower 12 bits, while the trailing linear interpolation factor is given as the lower 12 bits.

In Fig.6C, there is shown data  $D_{s_o}$  obtained on multiplying the linear interpolation factors with the two data  $D_{s_{a_i}}$ ,  $D_{s_{b_i}}$  at the interval of  $T_{s_i}/256$ .

Output data of the interpolation circuit 14 is 8  $F_{s_o}$  data. The 8  $F_{s_o}$  data is routed to a re-sampling frequency signal outputting circuit 19 which sub-samples the 8  $F_{s_o}$  data to produce 4  $F_{s_o}$  or 2  $F_{s_o}$  data. One of the 8  $F_{s_o}$ , 4  $F_{s_o}$  or 2  $F_{s_o}$  data is selected by a multiplexor 19a.

The band-limiting filter 20 is a filter for preventing aliasing noise from being produced in output data. If the input sampling frequency  $F_{s_i}$  is higher than the output sampling frequency  $F_{s_o}$ , there is a risk of the aliasing noise being produced, so that the output signal of the multiplexor 19a needs to be limited in bandwidth.

With the above-described sampling frequency converting device, the sampling frequency ratio detection circuit 24 of the control unit 26 detects the new sampling frequency ratio  $R_{n\text{ NEW}}$  represented by the formula (1), in which error accumulation is not induced, as shown in Fig.3, while the address control signal generating circuit 25 generates a control signal controlling the re-sampling time address and the interpolation factors from the new sampling frequency ratio  $R_{n\text{ NEW}}$ . Thus it is possible with the present sampling frequency converting circuit to perform sampling frequency conversion by stable interpolation by the interpolation circuit 14 without producing overflow or underflow in the re-sampling buffer memory 13 or increasing the capacity of the re-sampling buffer memory 13. In addition, the output signal  $D_{s_o}$  as an output signal having the sampling frequency  $F_{s_o}$  is free of aliasing.

A third embodiment of the present invention is now explained.

Similarly to the above-described first and second embodiments, the present third embodiment is directed to a sampling frequency converting device of re-sampling the sampling frequency  $F_{s_i}$  of the input signal  $D_{s_i}$  into the signal  $D_{s_o}$  having an arbitrary sampling frequency  $F_{s_o}$ , and realizes sampling frequency conversion in which the input system is completely asynchronous with respect to the output system, that is sampling frequency conversion at a free conversion ratio without the relation of synchronicity between input and output signals. In the following description, the sampling frequency  $F_{s_i}$  of the input signal  $D_{s_i}$  is referred to as the input sampling frequency  $F_{s_i}$ , while the arbitrary sampling frequency  $F_{s_o}$  is referred to as the output sampling frequency  $F_{s_o}$ . The schematic arrangement of the present third embodiment may be explained by referring to Fig.4 showing the schematic arrangement of the above-described second embodiment. The difference between the present third embodiment and the second embodiment resides in the practical arrangement and operation of the control

unit 26.

Although the third embodiment is now explained by referring to Fig.4 and newly to Figs.7 to 9; the following description is mainly centered about the practical construction and the operation of the control unit 26 for the above reason.

Referring to Fig.4, the sampling frequency converting circuit of the present third embodiment comprises an 8  $F_s$  over-sampling filter 12, a re-sampling buffer memory 13, an interpolation circuit 14, a control unit 26, a re-sampling frequency signal outputting circuit 19 and a band-limiting filter 20. The control unit counts the period  $t$  ( $= N \cdot T_{so}$ ) supplied at the input terminal 23 by the input master clocks  $MCK_i$  ( $= M \cdot F_{si}$ ) supplied at the input terminal 22 over a shorter time period  $t_s$  and a longer time period  $t_L$  to produce the current detected value  $R_{ns}$  and  $R_{nL}$  at the shorter time period  $t_s$  and a longer time period  $t_L$  and generates a new sampling frequency ratio  $R_{ns\ NEW}$  and new sampling frequency ratio  $R_{nL\ NEW}$  over a shorter time period  $t_s$  and a longer time period  $t_L$  based on the current detected values  $R_{ns}$  and  $R_{nL}$  and past detection values  $R_{ns-1}$  and  $R_{nL-1}$  preceding the current values by one detection period. The control unit also generates a control signal controlling the address signal of the re-sampling buffer memory 13 and the interpolation factors of the interpolation circuit 14 from one of the new sampling frequency ratio  $R_{ns\ NEW}$  and new sampling frequency ratio  $R_{nL\ NEW}$  and controls the re-sampling buffer memory 13 and the interpolation circuit 14 based on the generated address signal and the control signal to produce the sampling frequency conversion ratio.

The control unit 26 has a sampling frequency ratio detection circuit 24 and an address control signal generating circuit 25. The sampling frequency ratio detection circuit 24 detects the values of the current sampling frequency ratio  $R_{ns}$  and  $R_{nL}$  by counting the short-term period  $t_s$  and the long-term period  $t_L$  supplied from the input terminal 23 by the master clocks  $MCK_i$  ( $= M \cdot F_i$ ) supplied at the input terminal 22 and finds the values of the new sampling frequency ratio  $R_{ns\ NEW}$  and  $R_{nL\ NEW}$  over the short-term period  $t_s$  and the long-term period  $t_L$  based on the values of the current sampling frequency ratio  $R_{ns}$  and  $R_{nL}$ . The address control signal generating circuit 25 generates a control signal controlling the interpolation factor of the interpolation circuit 14 and the address signal of the re-sampling buffer memory 13 based on the values of the new sampling frequency ratio  $R_{ns\ NEW}$  and  $R_{nL\ NEW}$ .

Referring to Fig.7, the sampling frequency ratio detection circuit 24 includes a short-term counter 40 for counting the sampling period  $N_s \cdot T_{so}$  at the short time period  $t_s$  entering at the input terminal 23a by the input master clock  $MCK_i$  at an input terminal 23a, and an arithmetic-logic unit 41 for finding a new sampling frequency ratio  $R_{ns\ NEW}$  at the shorter period  $t_s$  based on the current sampling frequency ratio  $R_{ns}$  which is the count output of the short-term counter 40. The detection circuit 24 also includes a long-term counter 42 for counting the sampling period  $N_L \cdot T_{so}$  at the long time period  $t_L$  entering at the input terminal 23b by the input master clock  $MCK_i$  at an input terminal 23b, and an arithmetic-logic unit 43 for finding a new sampling frequency ratio  $R_{nL\ NEW}$  at the shorter period  $t_L$  based on the current sampling frequency ratio  $R_{nL}$  which is the count output of the long-term counter 42. The detection circuit 24 finally includes a comparator circuit 44 for comparing the new sampling frequency ratio  $R_{ns\ NEW}$  at the shorter period  $t_s$  as found by the arithmetic-logic unit 41, to the new sampling frequency ratio  $R_{nL\ NEW}$  at the shorter period  $t_L$  as found by the arithmetic-logic unit 43, and a selection circuit 45 responsive to the result of comparison at the comparator circuit 44 to select and output one of the new sampling frequency ratio  $R_{ns\ NEW}$  at the shorter period  $t_s$  or the new sampling frequency ratio  $R_{nL\ NEW}$  at the shorter period  $t_L$ .

The arithmetic-logic unit 41 doubles the current sampling frequency ratio  $R_{ns}$  to give  $2R_{ns}$  and subtracts the past sampling frequency ratio  $R_{ns-1}$  from  $2R_{ns}$  to find a new sampling frequency ratio  $R_{ns\ NEW}$  for the short period  $t_s$ . This is equivalent to adding a difference  $\Delta R_{ns}$  between the sampling frequency ratio  $R_{ns}$  at the current short period  $t_s$  and the past detection value  $R_{ns-1}$  preceding the current value of the sampling frequency ratio  $R_{ns}$  by one detection period, as shown in Fig.8. That is, the new sampling frequency ratio  $R_{ns\ NEW}$  for the short period  $t_s$  becomes

$$\begin{aligned} R_{ns\ NEW} &= R_{ns} + \Delta R_{ns} \\ &= R_{ns} + (R_{ns} - R_{ns-1}) = 2R_{ns} - R_{ns-1} \quad (2) \end{aligned}$$

On the other hand, the arithmetic-logic unit 43 doubles the current sampling frequency ratio  $R_{nL}$  to give  $2R_{nL}$  and subtracts the past sampling frequency ratio  $R_{nL-1}$  from  $2R_{nL}$  to find a new sampling frequency ratio  $R_{nL\ NEW}$  for the short period  $t_s$ . This is equivalent to adding a difference  $\Delta R_{nL}$  between the sampling frequency ratio  $R_{nL}$  at the current short period  $t_s$  and the past detection value  $R_{nL-1}$  preceding the current value of the sampling frequency ratio  $R_{nL}$  by one detection period, as shown in Fig.9. That is, the new sampling frequency ratio  $R_{nL\ NEW}$  for the short period  $t_s$  becomes

$$\begin{aligned} R_{nL\ NEW} &= R_{nL} + \Delta R_{nL} \\ &= R_{nL} + (R_{nL} - R_{nL-1}) = 2R_{nL} - R_{nL-1} \quad (3) \end{aligned}$$

The new sampling frequency ratio  $R_{ns\ NEW}$  of the short term  $t_s$ , as found by the arithmetic-logic unit 41, and the new sampling frequency ratio  $R_{nL\ NEW}$  of the long term  $t_L$ , as found by the arithmetic-logic unit 43, are

fed to the comparator 44. The comparator 44 determines whether or not the new sampling frequency ratio  $R_{ns\ NEW}$  for the short term  $t_s$  and the new sampling frequency ratio  $R_{nl\ NEW}$  for the long term  $t_l$  are coincident with each other within pre-set accuracy. That is, the comparator circuit 44 compares the new sampling frequency ratio  $R_{ns\ NEW}$  for the short term  $t_s$  having a larger number of bits to the new sampling frequency ratio  $R_{nl\ NEW}$  for the long term  $t_l$  having a smaller number of bits. Such comparison is made for a pre-set number of bits from the LSB of the new sampling frequency ratio  $R_{ns\ NEW}$  depending on the total number of bits of the new sampling frequency ratio  $R_{nl\ NEW}$  and the total number of bits of the new sampling frequency ratio  $R_{ns\ NEW}$ . In this manner, the two frequency ratio values may be discriminated as to the possible coincidence within a pre-set range. When the comparator circuit 44 finds that the new sampling frequency ratio  $R_{nl\ NEW}$  and the new sampling frequency ratio  $R_{ns\ NEW}$  are coincident with each other within preset accuracy, it issues a selection control signal to the selection circuit 45 to select and output the new sampling frequency ratio  $R_{nl\ NEW}$  for the long term. Conversely, when the comparator circuit 44 finds that the new sampling frequency ratio  $R_{nl\ NEW}$  and the new sampling frequency ratio  $R_{ns\ NEW}$  are not coincident with each other, it issues a selection control signal to the selection circuit 45 to select and output the new sampling frequency ratio  $R_{ns\ NEW}$  for the short term.

The selection circuit 45 is responsive to the selection control signal to select and output the new sampling frequency ratio  $R_{nl\ NEW}$  for the long term or the new sampling frequency ratio  $R_{ns\ NEW}$  for the short term.

The address control signal generating circuit 25 cumulatively adds the new sampling frequency ratio  $R_{nl\ NEW}$  or the new sampling frequency ratio  $R_{ns\ NEW}$  as selected by the selection circuit 45, using an addition circuit 46 and the flip-flop circuit 47 to generate data readout addresses at the re-sampling buffer memory 13. The address control signal generating circuit 25 also is responsive to the new sampling frequency ratio  $R_{nl\ NEW}$  or the new sampling frequency ratio  $R_{ns\ NEW}$  as selected by the selection circuit 45 to generate the selection control signal for the over-sampling factors employed for over-sampling carried out in the interpolation circuit 14 and the leading and trailing linear interpolation factors for linear interpolation (LIP.F.L and LIP.F.T.) and to transmit the generated signals to the interpolation circuit 14.

The flip-flop circuit 47 is preferably a D-flip-flop circuit. From the input terminal 48 are fed  $8F_{so}$  clocks which are in keeping with the sampling frequency of  $8F_{so}$  of the output signals of the present third embodiment. Of course, if the sampling frequency of the output signal is  $4F_{so}$ ,  $2F_{so}$ ,  $4F_{so}$  or  $2F_{so}$  clocks are transmitted. From the input terminal 49 are supplied initializing signals  $S_E$ .

Since the construction and operation of the interpolation circuit 14 are identical with those of the circuit shown in Figs.4 and 6, the corresponding description is omitted for simplicity.

With the sampling frequency converting device of the present third embodiment, the sampling frequency ratio detection circuit 24 outputs the new sampling frequency ratio  $R_{nl\ NEW}$  or the new sampling frequency ratio  $R_{ns\ NEW}$  which is free from error accumulation as in Figs.8 or 9, while the address control signal generating circuit 25 generates a control signal for controlling the re-sampling time address or the interpolation factors. Thus it is possible with the present third embodiment of the sampling frequency converting circuit to perform sampling frequency conversion by stable interpolation by the interpolation circuit 14 without producing overflow or underflow in the re-sampling buffer memory 13 or increasing the capacity of the re-sampling buffer memory 13. In addition, the output signal  $D_{so}$  as an output signal having the sampling frequency  $F_{so}$  is free of aliasing.

The fourth embodiment is now explained.

Since the present fourth embodiment differs from the above-described third embodiment only with respect to the control unit 26, the following description of the remaining components is not made for simplicity.

With the present fourth embodiment, the long-term counter 42 is omitted in constructing the sampling frequency ratio detection circuit 24 of the control unit 26, as shown in Fig.10, instead of providing the short term counter 40 and the long term counter 42, as in the above-described third embodiment.

The new sampling frequency ratio  $R_{ns\ NEW}$ , an output of the short-term sampling frequency ratio detection circuit 53 having the short term counter, is fed not only to a comparator circuit 57 and a selection circuit 58 but also to an addition circuit 54. The addition circuit 54, inherently employed in the address control signal generating circuit 25, as in the addition circuit 46 shown in Fig.7, may be employed time-divisionally. Thus the addition circuit 54 employs an accumulative addition latch 55 to cumulatively add the values of the new sampling frequency ratio  $R_{ns\ NEW}$  to adaptively produce the new sampling frequency ratio  $R_{nl\ NEW}$ . This new sampling frequency ratio  $R_{nl\ NEW}$  is fed via a long-term latch 56 to the comparator circuit 57 and to the selection circuit 58.

Thus, with the present fourth embodiment, the comparator circuit 57 determines whether or not the new sampling frequency ratio  $R_{ns\ NEW}$  at the short term  $t_s$  based on the count output obtained by counting the sampling frequency  $F_{si}$  of input signals at an input terminal 52 is coincident with the new sampling frequency ratio  $R_{nl\ NEW}$  at the long term  $t_l$  obtained on cumulative addition of the new sampling frequency ratio  $R_{ns\ NEW}$  using the addition circuit 54 and the cumulative addition latch 55 and counting using frequency-dividing clocks at the long-term latch 56 within pre-set accuracy, and the selection circuit 58 selects and outputs the new sam-

pling frequency ratio  $R_{nL\text{ NEW}}$  or the new sampling frequency ratio  $R_{nS\text{ NEW}}$  in case of coincidence and non-coincidence, respectively. The clock frequency divider 51 frequency-divides the reference clocks supplied at an input terminal 50 to transmit the resulting frequency-dividing clocks to a short-term sampling frequency ratio detection circuit 53, a cumulative addition-latch circuit 55 and to a long-term latch circuit 56. Thus it is possible  
 5 with the present fourth embodiment of the sampling frequency converting circuit to eliminate the long-term counter and to perform sampling frequency conversion by stable interpolation by the interpolation circuit 14 without producing overflow or underflow in the re-sampling buffer memory or increasing the capacity of the re-sampling buffer memory. In addition, the output signal  $D_{so}$  as an output signal having the sampling frequency  $F_{so}$  is free of aliasing.

10 A fifth embodiment is now explained.

With the present fifth embodiment, the sampling frequency ratio detection circuit 24 of the second embodiment shown in Fig.5 is configured as shown in Fig.11.

With the sampling frequency ratio detection circuit 24, employed in the present fifth embodiment of the sampling frequency converting device, a past detected value  $R_{n-1}$  preceding the current detection period by one detection period is subtracted from twice the current sampling frequency ratio  $R_n$  to find a new sampling frequency ratio  $R_{n\text{ NEW}}$ .  
 15

Thus, with the present fifth embodiment, the sampling frequency ratio  $F_{si}$  of an input signal at an input terminal 62 is counted by a reference sampling frequency ratio detection circuit 63 by the frequency-dividing clocks to produce the current sampling frequency ratio  $R_n$  which is then supplied via a D-flip-flop circuit 64 and an inverting circuit 65 to an addition circuit 67 and added by the addition circuit 67 via a bit shifter 66 to the sampling frequency ratio  $R_n$ . The bit shifter 66 produces a frequency ratio value twice the current frequency ratio, or  $2R_n$ , while the D-flip-flop circuit 64 and the inverting circuit 65 produce a frequency ratio value  $-R_{n-1}$  which is inverted in sign from the frequency ratio value  $R_{n-1}$  preceding the current sampling frequency  $R_n$  by one detection period. Thus the addition circuit 67 performs an arithmetic operation shown by the equation (1).  
 20  
 25 The clock frequency divider 61 routes the frequency-divided clocks, produced by frequency-dividing the reference clocks  $C_R$  supplied at the input terminal 60, to the reference sampling frequency circuit 63 and to the D-flip-flop circuit 64.

Thus, with the present fifth embodiment, the current sampling frequency ratio  $R_n$  is measured from the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$  and a new sampling frequency ratio  $R_{n\text{ NEW}}$  is found on the basis of the current detection value  $R_n$  and the past detected value  $R_{n-1}$ . Since it is possible with the address control signal generating circuit 25 to generate the re-sampling time addresses from the new sampling frequency ratio  $R_{n\text{ NEW}}$  free from error accumulation as in Fig.3, it becomes possible to perform sampling frequency conversion by stable interpolation by the interpolation circuit 14 without producing overflow or underflow in the re-sampling buffer memory 13 or increasing the capacity of the re-sampling buffer memory  
 30  
 35 13.

A sixth embodiment is now explained.

In the present sixth embodiment, the sampling frequency ratio detection circuit 24 employed in the second embodiment shown in Fig.5 is configured as shown in Fig.12.

A reference sampling frequency ratio detection circuit 73 detects the current sampling frequency ratio  $R_n$  by counting with the frequency-dividing clocks obtained on frequency-dividing the sampling frequency  $F_{si}$  of the input signal at an input terminal 72 by a frequency divider 71. The current sampling frequency ratio  $R_n$  is fed via a D-flip-flop circuit 74 and an inverter circuit 75 to an addition circuit 76 where it is added to the current sampling frequency ratio  $R_n$ . The D-flip-flop circuit 74 and the inverting circuit 75 generates a frequency ratio value  $-R_{n-1}$  inverted in sign from the value  $R_{n-1}$  preceding the current value  $R_n$  by one detection period. Thus the addition circuit 76 outputs a difference  $\Delta R_n$  between the current sampling frequency ratio  $R_n$  and the sampling frequency ratio  $R_{n-1}$  preceding the current value  $R_n$  by one detection period.  
 40  
 45

The difference  $\Delta R_n$  is fed to a multiplication circuit 77 and to an addition circuit 80. The multiplication circuit 77 multiplies the difference  $\Delta R_n$  with a coefficient  $k$  ( $k < 1$ ) and routes the resulting product to an addition circuit 78. An addition circuit 80 cumulatively adds to the difference  $\Delta R_n$  the output signals of the D-flip-flop 82 as later explained.  
 50

An output signal of the addition circuit 80 is fed to a multiplication circuit 81 so as to be multiplied by  $(1-k)$ . An output signal of the multiplication circuit 81 is fed to a D-flip-flop 82, which then counts the output signals of the multiplication circuit 81 based upon the frequency-divided clocks supplied from the clock frequency divider 71 to output a ratio value preceding the current ratio value by  $m$  detection periods. Thus a feedback circuit made up of the addition circuit 80, multiplication circuit 81 and the D-flip-flop circuit 82 becomes a circuit for finding an infinite series  $(1-k)^m(\Delta R_{n-m})$ .  
 55

The infinite series  $(1-k)^m(\Delta R_{n-m})$  of the feedback circuit is added to the result of multiplication  $k\Delta R_n$  from the multiplication circuit 77 at the addition circuit 78. An addition output of the addition circuit 78 is fed to an

addition circuit 79, which adds the addition output of the addition circuit 78 to the current sampling frequency ratio  $R_n$  to output a new sampling frequency ratio  $R_{n,NEW}$ .

The clock frequency divider 71 routes the frequency-divided clocks obtained on frequency dividing the reference clocks supplied from the input terminal 70 to the sampling frequency ratio detection circuit 73, D-flip-flop 74 and to the D-flip-flop circuit 82.

Thus, with the present sixth embodiment, the current sampling frequency ratio  $R_n$  is measured from the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$ , and  $k\Delta R_n$  from the D-flip-flop 74 and the inverting circuit 75 is summed to the infinite series (the sum of the output  $(1-k)^m(\Delta R_{n-m})$  of the feedback circuit made up of the addition circuit 80, the multiplication circuit 81 and the D-flip-flop 82, from  $m = 1$  up to  $m =$  infinite) to give the new sampling frequency ratio  $R_{n,NEW}$  as indicated by the following equation (4):

$$R_{n,NEW} = R_n + k\Delta R_n + \sum_{m=1}^{\infty} (1-k)^m (\Delta R_{n-m})$$

(4)

where  $\Delta R_n = R_n - R_{n-1}$  and  $k < 1$ .

With the present sixth embodiment, the new sampling frequency ratio  $R_{n,NEW}$  is outputted to the address control signal generating circuit 25. Since it is possible with the address control signal generating circuit 25 to generate the re-sampling time addresses from the new sampling frequency ratio  $R_{n,NEW}$  free from error accumulation as in Fig. 13, it becomes possible to perform sampling frequency conversion by stable interpolation by the interpolation circuit without producing overflow or underflow in the re-sampling buffer memory 13 or increasing the capacity of the re-sampling buffer memory 13.

Referring to Fig. 14, a seventh embodiment is now explained.

The seventh embodiment comprises a re-sampling buffer memory 102 for storing the input signal  $D_{si}$  of the input sampling frequency  $F_{si}$  entering at the input terminal 101, and an interpolation circuit 103 for interpolating readout signals from the re-sampling buffer memory 102. The seventh embodiment also comprises a sampling frequency ratio detection circuit 107 and a controller 108. The frequency ratio detection circuit detects the ratio of the input sampling frequency  $F_{si}$  supplied from the input terminal 105 to the output sampling frequency  $F_{so}$  from the input terminal 106 over a short time period and over a long time period. The controller 108 is responsive to the sampling frequency ratio over the short time period and to the sampling frequency ratio over the long time period from the detection circuit 107 to control the re-sampling buffer memory 102 and the interpolation circuit 103. The interpolation circuit 103, whose interpolating operation is controlled by the controller 108, outputs a signal  $D_{so}$  having the output sampling frequency  $F_{so}$  at the output terminal 104.

The sampling frequency ratio detection circuit 107 detects the sampling frequency ratio  $R_s$  and the sampling frequency ratio  $R_L$ , each of which is the ratio of the input sampling frequency  $F_{si}$  to the output sampling frequency  $F_{so}$  over the short time period and that over the long period, respectively.

The sampling frequency ratio detection circuit 107 detects whether or not the sampling frequency ratio  $R_s$  over the short time period and the sampling frequency ratio  $R_L$  over the long time period coincide with each other within pre-set accuracy. The detection circuit 107 selects the sampling frequency ratio  $R_L$  for detection over a long time period and the sampling frequency ratio  $R_s$  for detection over a short time period in case of coincidence and non-coincidence, respectively, and outputs the selected value to the controller 108.

The controller 108 is responsive to the sampling frequency ratio values  $R_L$  or  $R_s$  transmitted from the sampling frequency ratio detection circuit 107 to generate re-sampling time addresses as data readout addresses which are transmitted to the re-sampling buffer memory 102. On the other hand, the controller 108 is responsive to the sampling frequency ratio  $R_L$  or  $R_s$  to generate the selection control signal for the over-sampling factors employed in over-sampling performed by the interpolation circuit 103 and the leading and trailing linear interpolation factors and to transmit the generated signals to the interpolation circuit 103.

The interpolation circuit 103 reads out necessary data from the re-sampling buffer memory, based upon the above-mentioned re-sampling time addresses, generates two mutually adjacent high-order interpolation data associated with the re-sampling time addresses by, for example, FIR filtering, while processing the resulting data with linear interpolation and summing the resulting data to each other to generate a signal  $D_{so}$  having an output sampling frequency  $F_{so}$ .

The sampling frequency ratio detection circuit 107 detects whether or not the sampling frequency ratio  $R_s$  over the short time period and the sampling frequency ratio  $R_L$  over the long time period coincide with each other within pre-set accuracy. The detection circuit 107 selects the sampling frequency ratio  $R_L$  for detection

over a long time period and the sampling frequency ratio  $R_s$  for detection over a short time period in case of coincidence and non-coincidence, respectively, and outputs the selected value to the controller 108.

If the ratio between the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$  is detected over a short time period  $t_s$ , the error  $E_s$  becomes smaller as shown at A in Fig.15, thus enabling high-speed response to the error. However, the resolution becomes small to render it difficult to maintain high accuracy. Conversely, if the ratio between the input sampling frequency  $F_{si}$  and the output sampling frequency  $F_{so}$  is detected over a long time period  $t_l$ , the error  $E_l$  becomes larger as shown at B in Fig.15, thus enabling high resolution and high accuracy, although it becomes difficult to achieve high-speed response to the error. For this reason, the sampling frequency ratio detection circuit 107 detects whether or not the sampling frequency ratio  $R_s$  over the short time period and the sampling frequency ratio  $R_l$  over the long time period coincide with each other within pre-set accuracy. The detection circuit 107 selects the sampling frequency ratio  $R_l$  for detection over a long time period and the sampling frequency ratio  $R_s$  for detection over a short time period in case of coincidence and non-coincidence, respectively, and outputs the selected value to the controller 108.

Such detection within the pre-set accuracy may be achieved by comparing the sampling frequency ratio  $R_s$  over the short time period and the sampling frequency ratio  $R_l$  over the long time period only with respect to a pre-set range of bits. For example, in handling the sampling frequency ratio as the digital value, such comparison is made for a pre-set number of bits from the MSB of the sampling frequency ratio  $R_l$  corresponding to the total number of bits of the sampling frequency ratio  $R_s$  and the total number of bits of the sampling frequency ratio  $R_s$  with the smaller number of bits.

Consequently, the sampling frequency converting device of the present seventh embodiment adaptively changes over the high-speed re-sampling time address generation to the high-precision re-sampling time address generation or vice versa depending on the sampling frequency ratio, and performs the sampling frequency conversion responsive to the re-sampling time address generated with high precision if the variation in the sampling frequency is not produced within pre-set accuracy, while performing the sampling frequency conversion responsive to the re-sampling time address generated at a high speed if the variation in the sampling frequency is produced within pre-set accuracy. Thus it becomes possible with the present seventh embodiment to prevent the playback audio signals from being deteriorated due to the difference in the sampling frequencies and to realize mixing by free sampling frequency conversion.

Referring to Figs.16 and 17, an eighth embodiment is now explained.

The present eighth embodiment comprises an 8  $F_{si}$  over-sampling filter 112 for over-sampling the input signal  $D_{si}$  at the input terminal 111 of Fig. 16, with the input sampling frequency of  $F_{si}$ , to 8  $F_{si}$  for re-sampling, and a re-sampling buffer memory 113 for writing and reading the 8  $F_{si}$  input signal from the 8  $F_{si}$  over-sampling filter 112. The eighth embodiment also comprises an interpolation circuit 114 for interpolating the readout signals from the re-sampling buffer memory 113, and a sampling frequency ratio detection circuit 124. The sampling frequency ratio detection circuit 124 detects over a short time period and over a long time period, the sampling frequency ratio improved in resolution by counting the output sampling periods  $t$  ( $t = N \cdot T_{so}$ ) equal to  $N$  times the period of the output sampling frequency  $F_{so}$  supplied at the input terminal 123 by input reference clocks which is an integer number multiple of the sampling frequency  $F_{si}$  supplied at the input terminal 122 (input master clocks  $MCK_i$  equal to  $M \cdot F_{si}$ ). The eighth embodiment also comprises a controller 125, a re-sampling frequency signal outputting circuit 119 and a band-limiting filter 120. The controller 125 is responsive to the sampling frequency ratio over the short time period or that over a long time period, as detected by the sampling frequency ratio detection circuit 124, to control the re-sampling buffer memory 113 and the interpolation circuit 114. The re-sampling frequency signal outputting circuit 119 sub-samples the sampling frequency of the output signal of the interpolation circuit 114 having its operation of interpolation controlled by the controller 125 for converting the sampling frequency into the output sampling frequency  $F_{so}$  equal to 2, 4 and 8 times the frequency of the output signal of the interpolation circuit 114, and selects one of the values of the output sampling frequency  $F_{so}$  equal to 2, 4 and 8 times. The band-limiting filter 120 limits the bandwidth of the output signal of the re-sampling frequency signal outputting circuit 119 and outputs the output signal  $D_{so}$  having the output sampling frequency  $F_{so}$  at the output terminal 121.

The digital signal having the sampling frequency  $8F_{si}$ , produced by the 8  $F_{si}$  over-sampling filter 112, is fed to the re-sampling buffer memory 113, as described above. This re-sampling buffer memory 113 is a 20-bit 64-word buffer RAM, thus having a sampling frequency time eight times as large as the input sampling frequency time.

Referring to Fig.17, the sampling frequency ratio detection circuit 124 comprises a short-term counter 130 for counting the integer number multiple sampling period  $N_s \cdot T_{sc}$  at the short time period  $t_s$  entering the input terminal 123a, with the input master clocks  $MCK_i$  fed at the input terminal 122, and a latch 131 for latching the count output at the short-term counter 130 based on the sampling period  $N_s \cdot T_{sc}$ . The sampling frequency ratio detection circuit 124 comprises a long-term counter 132 for counting the integer number multiple sampling per-

iod  $N_L \cdot T_{sc}$  at the long time period  $t_L$  entering the input terminal 123b, with the input master clocks  $MCK_i$  fed at the input terminal 122, and a latch 133 for latching the count output at the long-term counter 132 based on the sampling period  $N_L \cdot T_{sc}$ . The sampling frequency ratio detection circuit 124 further comprises a comparator circuit 134 for comparing a latch output of the latch 131 to the latch output of the latch 132 and a selection circuit 135 for selecting and outputting one of the latch output at the controller 125 responsive to the result of comparison by the comparator circuit 134.

The short-term counter 130 counts the by the sampling period  $N_s \cdot T_{sc}$  with the input master clocks  $MCK_i$ , while the latch 131 latches the count results, for finding the sampling frequency ratio  $R_s$  over the short time period  $t_s$ . On the other hand, the long-term counter 132 counts the by the sampling period  $N_L \cdot T_{sc}$  with the input master clocks  $MCK_i$ , while the latch 133 latches the count results, for finding the sampling frequency ratio  $R_L$  over the long time period  $t_L$ . That is, the latch period by the latch 131 is the short term  $t_s$  and that by the latch 133 is the long term  $t_L$ . These latch periods  $t_s$  and  $t_L$  are selected so that the resolution of the sampling frequency ratio  $R_s$  is coincident with the error with respect to the real time of the sampling frequency ratio  $R_L$  during the conversion for the maximum assumed rate of change of the input/output sampling frequency ratio.

Meanwhile, the input master clock  $MCK_i$  is of a sufficiently higher rate than the sampling periods  $N_s \cdot T_{sc}$  or  $N_L \cdot T_{sc}$  and is of the frequency equal to M times the input sampling frequency  $F_{si}$ , where M is an integer.

The comparator circuit 134 determines whether or not the sampling frequency ratio  $R_s$  is coincident with the sampling frequency ratio  $R_L$  within pre-set accuracy. If the comparator circuit 134 finds that the sampling frequency ratio  $R_s$  is or is not coincident with the sampling frequency ratio  $R_L$ , the comparator circuit 134 transmits the corresponding selection control signal to the selection circuit 135.

The selection circuit 135 is responsive to the selection control signal supplied from the comparator circuit 135 to select and output the sampling frequency ratio  $R_s$  or  $R_L$  from the latch 131 or from the latch 133.

The comparator circuit 134 compares the sampling frequency ratio  $R_L$  having a larger number of bits to the sampling frequency ratio  $R_s$  having a smaller number of bits. For such comparison, a range of bits from the MSB of the sampling frequency ratio  $R_L$  as far as a pre-set bit corresponding to the total number of bits of the sampling frequency ratio  $R_s$  is compared to the total bits of the sampling frequency ratio  $R_s$ . Thus it becomes possible to detect the possible coincidence within the pre-set range. If the comparator circuit 134 finds that the sampling frequency ratio  $R_s$  is coincident with the sampling frequency ratio  $R_L$  within a pre-set range, the comparator circuit issues a selection control signal instructing the selection circuit 135 to select and output the sampling frequency ratio  $R_L$  at the longer period  $t_L$ . On the other hand, if the comparator circuit 134 finds that the sampling frequency ratio  $R_s$  is not coincident with the sampling frequency ratio  $R_L$  within a pre-set range, the comparator circuit issues a selection control signal instructing the selection circuit 135 to select and output the sampling frequency ratio  $R_s$  at the shorter period  $t_s$ .

The selection circuit 35 is responsive to the above-mentioned two selection control signal supplied from the comparator circuit 34 to output the sampling frequency ratio  $R_L$  at the longer period  $t_L$  or the sampling frequency ratio  $R_s$  at the shorter period  $t_s$  to an addition unit 136 of the controller 125.

Referring to Fig. 17, the controller 125 cumulatively adds the sampling frequency ratio  $R_s$  or  $R_L$  supplied from the sampling frequency ratio detection circuit 124, using the addition circuit 136 and the flip-flop circuit 139, for generating data readout addresses for the re-sampling buffer memory 113. On the other hand, the controller 125 generates, with the aid of the addition circuit 136 and the flip-flop circuit 139, the control signal for selecting the over-sampling factors to the interpolation circuit 114, and the leading and trailing linear interpolation factors (LIP.F.L. and LIP.F.T.).

The above data readout addresses, over-sampling factor selection control signal and the linear interpolation factors are outputted from the controller 25 as upper order bit range, mid order bit range and as lower order bit range, respectively.

The flip-flop circuit 137 preferably a D-flip-flop.  $8 F_{so}$  clocks are supplied from an input terminal 138 keeping with the sampling frequency  $8 F_{so}$  of the output signals of the eighth embodiment. If the sampling frequency of the output signals is 4 or  $2 F_{so}$ , 4 or  $2 F_{so}$  clocks are supplied, while an initializing signal  $S_E$  is supplied at an input terminal 35.

Referring to Fig. 16, the interpolation circuit 114 comprises a leading FIR filter L for the leading linear interpolation factor (LIP. F.L.) 15 and a trailing FIR filter for the trailing linear interpolation factor (LIP. F.T.) 17 for over-sampling data read out by the address control signal generating circuit 25 from the re-sampling buffer memory 113 in accordance with the re-sampling time addresses as data readout addresses supplied from the controller 125, as well as for processing the data with linear interpolation. The interpolation circuit also has a factor ROM 116 for supplying the over-sampling factors to the leading FIR filter for the leading linear interpolation factor 115 and the trailing FIR filter for the trailing linear interpolation factor 117 and an addition circuit 118 for adding an output signal of the leading FIR filter for the leading linear interpolation factor 115 and an output signal of the trailing FIR filter for the trailing linear interpolation factor 117. The factor ROM 16 has e.g.

32 24-bit 7-word over-sampling factors.

Output data of the interpolation circuit 14 is  $8 F_{so}$  data. The  $8 F_{so}$  data is routed to a re-sampling frequency signal outputting circuit 119 which sub-samples the  $8 F_{so}$  data to produce  $4 F_{so}$  or  $2 F_{so}$  data. One of the  $8 F_{so}$ ,  $4 F_{so}$  or  $2 F_{so}$  data is selected by the multiplexor 119a.

5 The band-limiting filter 120 is a filter for preventing aliasing noise from being produced in output data. If the input sampling frequency  $F_{si}$  is higher than the output sampling frequency  $F_{so}$ , there is a risk of the aliasing noise being produced, so that the output signal of the multiplexor 119a needs to be limited in bandwidth.

Consequently, the sampling frequency converting device of the present eighth embodiment adaptively changes over the high-speed re-sampling time address generation to the low-precision re-sampling time address generation or vice versa depending on the sampling frequency ratio, and performs the high accuracy sampling frequency conversion in case there is no substantial variation in the sampling frequency, while performing high-speed sampling frequency conversion in case there is any substantial variation in the sampling frequency, thus assuring compatibility between two inherently incompatible conversions of the high accuracy conversion and the high speed conversion.

15 Referring to Fig. 18, a ninth embodiment is now explained.

In the present ninth embodiment, the sampling frequency ratio  $R_s$  of the short-term sampling frequency ratio detection circuit 143 having the short-term counter is cumulatively added by time-divisionally employing the addition circuit 144 for generation of the re-sampling time address generation of the controller for producing an adaptive sampling frequency ratio  $R_n$ , without independently providing the short-term counter 130 and the long term counter 132, as in the eighth embodiment, thus enabling omission of the long-term counter.

20 That is, with the present ninth embodiment, a comparator circuit 147 detects whether or not the sampling frequency ratio  $R_s$  over the short period  $t_s$  as found by counting the sampling frequency  $F_{si}$  of the input signal at the input terminal 142 by the clocks supplied from the clock frequency divider 141 is or is not coincident with the sampling frequency ratio  $R_L$  over the long period  $t_L$  as found by cumulatively adding the sampling frequency  $R_s$  using an addition circuit 144 and a cumulative addition latch 145 followed by counting using frequency-divided clocks by a long-term latch 146. In case of non-coincidence, the sampling frequency ratio  $R_L$  over the long period  $t_L$  is selected by the selection circuit 148, whereas, in case of coincidence, the sampling frequency ratio  $R_s$  over the short period  $t_s$  is selected by the selection circuit 148. The selected frequency ratio is outputted to a controller. It is noted that the clock frequency divider 141 divides the frequency of the reference clocks  $C_R$  supplied from the input terminal 140 and clocks thus generated are routed to a short-term frequency ratio detection circuit 143, the cumulative addition latch circuit 145 and to the long-term latch circuit 146.

Thus the present ninth embodiment eliminates the long-term counter and is responsive to the sampling frequency ratio to be adaptively changed over between high-precision generation and high-speed generation of the re-sampling time addresses, in such a manner that high precision sampling frequency conversion and high speed sampling frequency conversion are performed in case there is not any significant variation in the sampling frequency and in case there is any significant variation in the sampling frequency, respectively.

Meanwhile, the ring-shaped buffer memories schematically shown in Fig. 19 may be employed as the re-sampling buffer memories 2, 13, 102 and 113 employed in the first to ninth embodiments.

That is, the re-sampling buffer memories 2, 13, 102 and 113 may be configured as a ring-shaped  $8 F_s$  20-bit 64-word data re-sampling buffer memory as shown in Fig. 19. The manner of controlling the ring-shaped  $8 F_s$  data re-sampling buffer memory is explained subsequently.

In the first to ninth embodiments, data writing and readout on or from the ring-shaped  $8 F_s$  data re-sampling buffer memory is controlled by the memory control signal generating circuit 8 and 25 and the controllers 108 and 125. Thus the controllers 108 and 125 shown in Figs. 14 and 16 supply data readout and data write addresses to the re-sampling buffer memories 102, 113 each designed as the  $8 F_s$  data re-sampling ring buffer memory, while also supplying data readout addresses to the re-sampling buffer memories 102, 113 from the sampling frequency ratio as detected by the sampling frequency ratio detection circuits 107, 124 for controlling the writing and readout of the re-sampling buffer memories 102, 113. Thus the controllers 108, 125 and the sampling frequency ratio detection circuits 107, 124 represent memory address controllers controlling the addresses of the re-sampling buffer memories 102, 113 and interpolation circuits controlling the interpolation circuits 103, 114.

Referring to Fig. 20, the memory address controlling device made up of a sampling frequency ratio detection circuit 124 and the controller 125 will be explained.

55 The memory address controlling device controls the readout addresses of the re-sampling buffer memory 113, which is a ring buffer memory for continuously recording and reproducing data on or from the recording medium, with the difference of the readout addresses being arbitrarily changed with respect to the write addresses. The main address controlling device comprises a controller 125 made up of an address difference detection circuit 132 for detecting the difference between the write address and the read-out address and an

address optimizing control circuit 134 for effecting optimal control on the readout address for controlling the address difference as detected by the address difference detection circuit 132, and a sampling frequency ratio detection circuit 124.

The sampling frequency ratio detection circuit 124 has a counter 130 for counting the multiple-number sampling period  $N \cdot T_{so}$  at the time period  $t$  entering the input terminal 123 by the input master clocks  $MCK_i$  supplied from the input terminal 122, and a latch 131 for latching the count output of the counter 130 based on the multiple-number sampling period  $N \cdot T_{so}$ .

The counter 130 counts the multiple-number sampling period  $N \cdot T_{so}$  by the input master clocks  $MCK_i$  and latches the result of count by the latch 131 to find the current sampling frequency ratio  $R$  at the period  $t$ .

The controller 125 includes, in addition to the address difference detection circuit 132 and the address optimization controlling circuit 134, an addition circuit 135 for adding output signals of the address optimization control circuit 135 to the sampling frequency ratio  $R$  from the latch 131 responsive to the address difference as detected by the address difference detection circuit 132, an addition circuit 136 for cumulatively adding the addition outputs of the addition circuit 135 and a flip-flop circuit 137.

The flip-flop circuit 137 is preferably a D-flip-flop.  $8 F_{so}$  clocks are supplied from an input terminal 138 in keeping with the sampling frequency  $8 F_{so}$  of the output signals of the second embodiment. If the sampling frequency of the output signals is  $4$  or  $2 F_{so}$ ,  $4$  or  $2 F_{so}$  clocks are supplied, while an initializing signal  $S_E$  is supplied at an input terminal 139.

The address difference detection circuit 132 adds the write address from an inverter 140 shown in Fig.21 to the readout address to find the difference between the readout address and the write address. Such difference between the readout address and the write address represents a measure indicating the allowance of the re-sampling buffer memory 113. If the address difference is depleted, an overflow state is produced in the re-sampling buffer memory 113.

The address difference optimization control circuit 134 is a control circuit for optimizing the readout address so that the address difference as detected by the address difference detection circuit 132 is controlled to an optimum value, and comprises an area decoder and latch 134a, a D-flip-flop 134b and an address optimizing encoder 134c, as shown in Fig.21.

The address difference optimization control circuit 134 decodes the address difference as detected by the address difference detection circuit 132 and causes the area decoder and latch 134a and the D-flip-flop 134b to latch and monitor at a certain period which area the detected address difference occupies with respect to an absolute maximum point of the write/readout address difference  $CT$ . The address difference optimization control circuit 134 is responsive to the monitored result to generate in the address optimizing encoder 134c a correction value to be added by the addition circuit 135 to the sampling frequency ratio  $R$  as detected by the sampling frequency ratio detection circuit 124.

If, for example, the re-sampling buffer memory 13 is a ring  $8 F_s$  data re-sampling buffer memory having the capacity of 20 bits and 64 words, as shown in Fig.19, the memory address controlling device controls the readout address  $A_r$  so that the data write address  $A_w$  and the data readout address  $A_r$  are in operation with a phase difference of  $180^\circ$  with the word difference of 32. Meanwhile, the memory address control device has eight  $F_{si}T$  data domain address with a point of  $4F_{si}T$  being  $CT$ .

If the address difference detected by the address difference detection circuit 132 is in a range of from  $CT - 0.5 F_{si}T$  to  $CT + 0.5 F_{si}T$ , that is in a range of from  $180 \pm 0.5 T_{si}$  ( $\pm 8 F_{si}$  samples), on the abscissa of Fig.22, the address optimization control circuit 134 of the memory address control device outputs a 0 output correction value to the addition circuit 135. Thus the memory address control device cumulatively adds only the sampling frequency ratio  $R$  as detected by the sampling frequency ratio detection circuit 124 by the addition circuit 136 and the D-flip-flop circuit 137 to generate the memory readout addresses. If the address difference detected by the address difference detection circuit 132 is not in the range of from  $CT - 0.5 F_{si}T$  to  $CT + 0.5 F_{si}T$ , that is in the range of from  $180 \pm 0.5 T_{si}$  ( $\pm 8 F_{si}$  samples), the address optimization control circuit 134 adds the correction value from the address optimization encoder 134c to the sampling frequency ratio  $R$ , until the absolute value of the address difference becomes equal to the maximum value  $CT$  ( $= 180^\circ$ ), by incrementing or decrementing the readout address. In addition, the circuit 132 cumulatively adds the correction value by the addition circuit 136 and the D-flip-flop circuit 137 to generate the memory readout addresses.

Specifically, if the address difference as detected by the address difference detection circuit 132 is in a range of from  $CT - 0.5 F_{si}T$  to  $2 F_{si}T$ , as plotted on the abscissa of Fig.21, the address optimization control circuit 134 adds a correction value to the sampling frequency ratio  $R$  at the addition circuit 135. The correction value is set so as to be twice the LSB of an imaginary set readout address or a virtual readout address. If the address difference is from  $CT - 2 F_{si}T$  to  $CT - 2 F_{si}T$ , the circuit 134 adds a correction value optimized from 256 times the LSB of the virtual address to the sampling frequency ratio  $R$ . If the address difference is from  $CT - 3 F_{si}T$  to  $CT - 2 F_{si}T$ , the circuit 134 adds a correction value optimized from 32768 times the LSB of the virtual address

to the sampling frequency ratio R.

On the other hand, if the address difference as detected by the address difference detection circuit 32 is in a range of from  $CT+0.5 F_{SiT}$  to  $CT+2 F_{SiT}$ , the address optimization control circuit 134 adds (or effectively subtracts) an inverted correction value optimized from twice the LSB of the virtual address to the sampling frequency ratio R in the addition circuit 135. If the address difference is in a range of from  $CT+2 F_{SiT}$  to  $CT+3 F_{SiT}$ , the address optimization control circuit 134 adds (or effectively subtracts) an inverted correction value optimized from 256 times the LSB of the virtual address to the sampling frequency ratio R in the addition circuit 135. On the other hand, if the address difference is in a range of from  $CT+3 F_{SiT}$  to  $CT+4 F_{SiT}$ , the address optimization control circuit 134 adds (or effectively subtracts) an inverted correction value optimized from 32768 times the LSB of the virtual address to the sampling frequency ratio R in the addition circuit 135.

That is, the address optimization control circuit 134 corrects the readout addresses until the phase difference becomes equal to 180 by adding or subtracting 1 at the second bit from the LSB of the virtual readout address when the address difference as detected by the address difference detection circuit 132, that is the readout phase, is deviated to  $\pm 2 T_{Si}$  from  $180 \pm 0.5 T_{Si}$ ; by adding or subtracting 1 at the eighth bit of the virtual address when the readout phase is deviated to  $180 \pm 3 T_{Si}$  or more from  $180 \pm 2 T_{Si}$  and by adding or subtracting 1 at the 15th bit when the readout phase is deviated by  $180 \pm 3 T_{Si}$  or more.

Thus the memory address control device sets an optimum phase at a high speed by employing a large correction value when the readout address phase is advanced or retarded significantly during power on time or during switching of the input signals or the output sampling frequency, while setting an optimum phase without signal deterioration by employing a medium correction value when the address phase is advanced or retarded to a moderate extent during change of the sampling frequency. On the other hand, if the address phase is advanced or retarded only slightly, the memory address control device sets an optimum phase without signal deterioration by employing a small correction value. That is, the high-speed correction and high-precision conversion can be used with compatibility by exploiting an optimum correction value depending on the state of signal deviation.

## Claims

1. A device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising
  - storage means for storing the input signal,
  - interpolation means for interpolating the signal read out from said storage means, and
  - control means for generating a first sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency and a second sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency based on said first sampling ratio for suppressing jitter components and for performing sampling frequency conversion, said control means generating a control signal for controlling the address signal of said storage means and the interpolation factors of said interpolation means and effecting sampling frequency conversion by controlling said storage means and the interpolation means based on the generated address signal and said control signal.
2. The device as claimed in claim 1, wherein said control means has sampling frequency ratio detection means for detecting said first sampling frequency ratio and said second sampling frequency ratio over a short time period and over a long time period, said control means controlling said storage means and said interpolation means based on said second sampling frequency ratio of said sampling frequency ratio detection means over the short time period and over the long time period.
3. The device as claimed in claim 1 wherein said sampling frequency ratio detection means checks the coincidence or non-coincidence within pre-set accuracy of the second sampling frequency ratio over the short time period and the second sampling frequency ratio over the long time period and selectively outputs the second frequency ratio over the long time period if the second frequency ratio over the short time period is coincident with the second sampling frequency ratio over the long time period; said sampling frequency ratio detection means selectively outputting the second frequency ratio over the short time period if the second frequency ratio over the short time period is not coincident with the second sampling frequency ratio over the long time period.
4. The device as claimed in claim 1 wherein said sampling frequency ratio detection means has a first coun-

ter for counting the period equal to an integer number multiple of the arbitrary sampling frequency based on clocks of an integer number multiple of the sampling frequency of the input digital signals over said short period of time, a second counter for counting the period of the arbitrary sampling frequency based on clocks of an integer number multiple of the sampling frequency of the input digital signals over said short period of time, a first arithmetic-logic unit for calculating the second sampling frequency ratio based on said first sampling frequency ratio over said short time period as counted by said first counter, a second arithmetic-logic unit for calculating the second sampling frequency ratio based on said first sampling frequency ratio over said long time period as counted by said second counter, a comparator for comparing said second sampling frequency ratio over said long period of said second arithmetic-logic unit to said second sampling frequency ratio over said short period of said first arithmetic-logic unit, and a selection unit for selectively outputting said second sampling frequency ratio over said long period of said second arithmetic-logic unit or said second sampling frequency ratio over said short period of said first arithmetic-logic unit based on the results of comparison from said comparator.

5. The device as claimed in claim 1 wherein said sampling frequency ratio detection means has a first frequency ratio detection unit for counting the sampling frequency of the input digital signal based on clocks divided in frequency from a reference clock for finding the sampling frequency ratio over said short time period, and a second frequency ratio detection unit for cumulatively adding the sampling frequency ratio from said first frequency ratio detection unit and counting the resulting sum with clocks divided in frequency from the reference clocks for detecting said sampling frequency ratio over said long period.
6. The device as claimed in claim 1 wherein said interpolation means is constituted by an FIR filter.
7. The device as claimed in claim 1 wherein said control means has sampling frequency ratio detection means for detecting the sampling frequency ratio between the sampling frequency of the input signal and said arbitrary sampling frequency and detecting a new sampling frequency ratio based on the resulting detected value and a past detected value, said control means controlling said storage means and said interpolation means based on the new sampling frequency ratio from said sampling frequency ratio detection means.
8. The device as claimed in claim 7 wherein said sampling frequency ratio detection means has finds the new sampling frequency ratio  $R_{n \text{ NEW}}$  by:
 
$$R_{n \text{ NEW}} = 2R_n - R_{n-1}$$
 that is by subtracting the past sampling frequency ratio  $R_{n-1}$  from  $2R_n$ , where  $r_n$  is the current sampling frequency ratio.
9. The device as claimed in claim 7 wherein said sampling frequency ratio detection means has a counter for counting the period equal to an integer number multiple of the period of the arbitrary sampling frequency based on clocks of an integer number multiple of the sampling frequency of the input digital signal and an arithmetic-logic unit for latching the results of count of said counter to find the current sampling frequency ratio and for calculating a new sampling frequency ratio from said current sampling frequency ratio and a past sampling frequency ratio preceding the current sampling frequency ratio by one detection period.
10. The device as claimed in claim 8 wherein said sampling frequency ratio detection means has a first counter for counting the period equal to an integer number multiple of the arbitrary sampling frequency based on clocks of an integer number multiple of the sampling frequency of the input digital signals over said short period of time, a second counter for counting the period of the arbitrary sampling frequency based on clocks of an integer number multiple of the sampling frequency of the input digital signals over said short period of time, a first arithmetic-logic unit for calculating a new sampling frequency ratio over a short time period based on said current sampling frequency ratio over said short time period as counted by said first counter and a past sampling frequency ratio preceding the current sampling frequency ratio by one detection period, a second arithmetic-logic unit for calculating a new sampling frequency ratio based on said current sampling frequency ratio over said long time period as counted by said second counter and a past sampling frequency ratio preceding the current ratio by one detection period, a comparator for comparing said new sampling frequency ratio over said long period of said second arithmetic-logic unit to said new sampling frequency ratio over said short period of said first arithmetic-logic unit, and a selection unit for selectively outputting said new sampling frequency ratio over said long period of said second arithmetic-logic unit or said new sampling frequency ratio over said short period of said first arithmetic-logic

unit based on the results of comparison from said comparator.

11. The device as claimed in claim 1 wherein said sampling frequency ratio detection means has a first frequency ratio detection unit for counting the sampling frequency of the input digital signal based on clocks divided in frequency from a reference clock for finding the current sampling frequency ratio over said short time period, and a second frequency ratio detection unit for cumulatively adding the sampling frequency ratio from said first frequency ratio detection unit and counting the resulting sum with clocks divided in frequency from the reference clocks for detecting said current sampling frequency ratio over said long period.
12. The device as claimed in claim 8 wherein said sampling frequency ratio detection means has a reference frequency ratio detection unit for finding a reference sampling frequency ratio based on the sampling frequency of the input digital signal based on clocks divided in frequency from the reference clocks, a first generator for generating a sampling frequency ratio preceding the current value by one detection period based on the sampling frequency ratio from said reference frequency ratio detection unit, a second generator for generating a sampling frequency ratio equal to twice the sampling frequency ratio from said first frequency ratio detection unit, and an addition unit for summing the sampling frequency ratio from said first generator and the sampling frequency ratio from said second generator.

13. The device as claimed in claim 7 wherein said sampling frequency ratio detection means finds the new sampling frequency ratio  $R_{n, \text{NEW}}$  by an equation

$$R_{n, \text{NEW}} = R_n + k \Delta R_n + \sum_{m=1}^{\infty} (1-k)^m (\Delta R_{n-m})$$

by summing the current sampling frequency ratio  $R_n$ ,  $k \Delta R_n$  ( $k < 1$ ), where  $\Delta R_n$  is the difference between the current frequency ratio  $R_n$  and a past detected value  $R_{n-1}$ ; and an infinite series of from  $m = 1$  to infinite of  $(1-k)^m (\Delta R_{n-m})$ .

14. The device as claimed in claim 13 wherein said sampling frequency ratio detection means has a reference frequency ratio detection unit for generating a reference sampling frequency ratio by counting the sampling frequency of the input digital signal by clocks divided in frequency from the reference clocks, a first generator for generating a sampling frequency ratio preceding the current value by one period based on the sampling frequency ratio from said reference frequency ratio, a detection unit for detecting a sampling frequency ratio from the frequency ratio detection unit and the sampling frequency ratio from said first generator, a second generator for generating a sampling frequency ratio preceding the current value by  $m$  periods based on an output of said detection unit, a first addition unit for adding the sampling frequency ratio from said second generator to the output of the detection unit, and a second addition unit for adding the output of the first addition unit to the output of the frequency ratio detection unit.
15. The device as claimed in claim 1 wherein said storage means record and reproduce data with the difference between the write address and the readout address being arbitrarily changed and wherein said control means has memory address control means for controlling the readout from the storage means responsive to the sampling frequency ratio between the sampling frequency of the input digital signal and said arbitrary sampling frequency.
16. The device as claimed in claim 1 wherein said memory address control means has a counter for counting the period equal to an integer number multiple of the period of the arbitrary sampling frequency based on clocks having a clock frequency equal to an integer number multiple of the arbitrary sampling frequency, a holding unit for finding the current sampling frequency ratio based on the counted result of the counter, an address difference detection unit for detecting a difference between the write address and the readout address, an address optimization control unit for controlling the address difference as detected by the address difference detection unit to an optimum value, and an addition unit for adding an output of said address optimization control unit to an output of said holding unit, an output of said holding unit being supplied to said control means.
17. A device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising

storage means for storing the input signal,  
 interpolation means for interpolating the signal read out from said storage means,  
 sampling frequency ratio detection means for detecting the sampling frequency ratio between the  
 sampling frequency of the input signal and the arbitrary sampling frequency over a short term and over  
 a long term, and

control means for controlling said storage means and the interpolation means responsive to the  
 sampling frequency ratio over the short time period and the sampling frequency ratio over the long time  
 period from said sampling frequency ratio detection means.

18. The device as claimed in claim 1 wherein said sampling frequency ratio detection means check for coin-  
 cidence or non-coincidence between the detection value over the short period and the detection value  
 over the long period within pre-set accuracy and selectively outputs the detected value over the long per-  
 iod when the detected value over the long period coincides with the detected value over the short period,  
 said sampling frequency detection means selectively outputting the detected value over the short period  
 when the detected value over the long period is not coincident with the detected value over the short per-  
 iod.

19. The device as claimed in claim 17 wherein said sampling frequency ratio detection means counts the per-  
 iod of one of the sampling frequencies with clocks equal to an integer number multiple of the other of the  
 sampling frequencies at a sufficiently high speed relative to the period of said one of the sampling fre-  
 quency of the input signal and the arbitrary sampling frequency.

20. The device as claimed in claim 17 wherein said interpolation means find two adjacent over-sampling data  
 by over-sampling a signal read out by said control means from said storage means responsive to control  
 signals supplied from said control means, said interpolation means also processing said two over-  
 sampling data with linear interpolation.

21. The device as claimed in claim 17 wherein, when the sampling frequency of the input signals is higher  
 than said arbitrary sampling frequency, an output signal of said interpolation means is limited in band-  
 width.

22. The device as claimed in claim 17 wherein said storage means record and reproduce data with the dif-  
 ference between the write address and the readout address being arbitrarily changed and wherein said  
 control means has memory address control means for controlling the readout from the storage means  
 responsive to the sampling frequency ratio between the sampling frequency of the input digital signal and  
 said arbitrary sampling frequency.

23. A device for converting the sampling frequency of an input signal into an arbitrary sampling frequency,  
 comprising

storage means for storing the input signal,  
 interpolation means for interpolating the signal read out from said storage means,  
 sampling frequency ratio detection means for detecting the sampling frequency ratio between the  
 sampling frequency of the input signal and the arbitrary sampling frequency and for detecting a new sam-  
 pling frequency ratio based on the detected value and a past detected value, and  
 control means for controlling said storage means and said interpolation means based on the new  
 sampling frequency ratio from said sampling frequency ratio detection means.

24. The device as claimed in claim 23 wherein said sampling frequency ratio detection means has finds the  
 new sampling frequency ratio  $R_{n\text{ NEW}}$  by

$$R_{n\text{ NEW}} = 2R_n - R_{n-1}$$

that is by subtracting the past sampling frequency ratio  $R_{n-1}$  from  $2R_n$ , where  $r_n$  is the current sampling  
 frequency ratio.

25. The device as claimed in claim 23 wherein said sampling frequency ratio detection means finds the new  
 sampling frequency ratio  $R_{n\text{ NEW}}$  by an equation

$$R_{n\text{ NEW}} = R_n + k \Delta R_n + \sum_{m=1}^{\infty} (1-k)^m (\Delta R_{n-m})$$

by summing the current sampling frequency ratio  $R_n$ ,  $k\Delta R_n$  ( $k < 1$ ), where  $\Delta R_n$  is the difference between the current frequency ratio  $R_n$  and a past detected value  $R_{n-1}$ , and an infinite series of from  $m = 1$  to infinite of  $(1-k)^m(\Delta R_{n-m})$ .

- 5 26. The device as claimed in claim 23 wherein said sampling frequency ratio detection means counts the period of one of the sampling frequencies with clocks equal to an integer number multiple of the other of the sampling frequencies at a sufficiently high speed relative to the period of one of the sampling frequency of the input signal and the arbitrary sampling frequency.
- 10 27. The device as claimed in claim 23 wherein said interpolation means find two adjacent over-sampling data by over-sampling a signal read out by said control means from said storage means responsive to control signals supplied from said control means, said interpolation means also processing said two over-sampling data with linear interpolation.
- 15 28. The device as claimed in claim 23 wherein, when the sampling frequency of the input signals is higher than said arbitrary sampling frequency, an output signal of said interpolation means is limited in bandwidth.
- 20 29. The device as claimed in claim 23 wherein said sampling frequency ratio detection means detects a sampling frequency ratio between the sampling time period of the input signal and the arbitrary sampling frequency over a short time period and over a long time period; said detection means detecting new sampling frequency ratio values over the short time period and over the long time period, responsive to the current detected value and the past detected value over the short time period and over the long time period; said detection means selectively outputting detected two new sampling frequency ratios.
- 25 30. The device as claimed in claim 23 wherein said sampling frequency ratio detection means check for coincidence or non-coincidence between the new sampling frequency ratio over the short period and the new sampling frequency ratio over the long period within pre-set accuracy and selectively outputs the sampling frequency ratio over the long period when the detected value over the long period coincides with the detected value over the short period, said sampling frequency detection means selectively outputting the sampling frequency ratio over the short period when the detected value over the long period is not coincident with the detected value over the short period.
- 30 31. The device as claimed in claim 23 wherein said storage means record and reproduce data with the difference between the write address and the readout address being arbitrarily changed and wherein said control means has memory address control means for controlling the readout from the storage means responsive to the sampling frequency ratio between the sampling frequency of the input digital signal and said arbitrary sampling frequency.
- 35 32. A device for converting the sampling frequency of an input signal into an arbitrary sampling frequency, comprising
  - 40 storage means for storing the input signal with the difference between the write address and the readout address being changed arbitrarily,
  - interpolation means for interpolating the signal read out from said storage means, and
  - memory address control means for controlling the readout from said storage means responsive to
    - 45 the sampling frequency ratio between the sampling frequency of the input signal and the arbitrary sampling frequency.
- 50 33. The device as claimed in claim 23 wherein said memory address control means has address difference detection means for detecting the difference between the write address and the readout address and address optimization control means for optimally controlling the address difference detected by said address difference detection means.
- 55 34. The device as claimed in claim 23 wherein said address optimization control means of said memory address control means generates readout addresses based on the absolute value of the address difference as detected by said address difference detection means.
35. A memory address control device for a ring buffer memory for recording and reproducing data, with the difference of the readout address being arbitrarily changed with respect to the write address, comprising

address difference detection means for detecting the difference between the write address and the readout address of the ring buffer memory, and

readout address optimization control means for optimally controlling the readout address for controlling the address difference detected by said address difference detection means.

5

36. The memory address control device as claimed in claim 34 wherein said readout address optimization control means generates the readout address based on the absolute value of the address difference as detected by said address difference detection means.
